INTRODUCTION

In the United States, approximately 16 million persons have type 2 diabetes mellitus. Diabetes is associated with increased morbidity from vascular disease. Hyperglycemia is thought to increase the risk of these vascular complications and, in the United Kingdom Prospective Diabetes Study, intensive treatment with diet, insulin, or oral hypoglycemic medications reduced the risk of microvascular complications by about 25%. While the optimal level of glycemic control is not known, most practice guidelines recommend that pharmacologic treatment be initiated in patients who have a fasting glucose level > 140 mg/dL or a HbA1c value >8% despite efforts at dietary control.

The oral hypoglycemics addressed in this review are listed in Table 1. Sulfonylureas are a class of oral drugs that reduce blood glucose levels by stimulating insulin secretion. The elevated insulin levels reduce hepatic glucose production and increase muscle glucose uptake. First-generation sulfonylureas available in the U.S. include chlorpropamide, tolazamide, and tolbutamide. Second-generation sulfonylureas available in the U.S. are glipizide, glimepiride, and glyburide (also called glibenclamide). An extended release form of glipizide is also available. In the U.S., glyburide is available under several trade names, including Micronase, DiaBeta, and Glynase. Glynase, a micronized form of glyburide, has different dosage and duration of action than the nonmicronized preparations. Because these products are labelled differently by the FDA, for the purposes of this review we considered them to be different drugs. Two other oral antidiabetic drugs that work by stimulating insulin secretion, repaglinide and nateglinide, are available in the U.S. These drugs have been called “non-sulfonylurea secretagogues.”

In 2002, the Oregon Health Resources Commission (OHRC) and the Washington State DUEC requested a review of the sulfonylureas and non-sulfonylurea secretagogues available in the U.S. as of March 1, 2003. Specifically, the OHRC requested information about whether there is evidence that one or more of these drugs is superior to others in terms of efficacy and safety.
**Scope and Key Questions**

The Oregon Evidence-based Practice Center developed the scope of the review by writing preliminary key questions, identifying the populations, interventions, and outcomes of interest and based on these, the eligibility criteria for studies. These were reviewed by an Oregon Health Resources Commission subcommittee comprised of local experts (pharmacists, physicians, and consumers) in public meetings and refined based on their input. In consultation with the subcommittee, we selected the following key questions to guide this review:

1. For adult patients with Type 2 diabetes, do oral hypoglycemics differ in the ability to reduce HbA1C levels?
2. For adult patients with Type 2 diabetes, do oral hypoglycemics differ in the progression or occurrence of clinically relevant outcomes?
3. For adult patients with Type 2 diabetes, do oral hypoglycemics differ in safety or adverse effects?
4. Are there subgroups of patients based on demographics (age, racial groups, gender), concomitant medications, co-morbidities (i.e. obesity), or history of hypoglycemic episodes for which one oral hypoglycemic is more effective or associated with fewer adverse effects?

**METHODS**

**Literature Search**

To identify articles relevant to each key question, we searched the Cochrane Library (2002, Issue 1), MEDLINE (1966-2002), EMBASE (1980-2001), and reference lists of review articles. In electronic searches, we combined terms for relevant research designs (see Appendix A for complete search strategy). Subcommittee members were invited to provide additional citations. Pharmaceutical manufacturers were invited to submit dossiers, including citations, using a protocol issued by the State of Oregon ([http://www.ohppr.state.or.us/index.htm](http://www.ohppr.state.or.us/index.htm)). All citations were imported into an electronic database (EndNote 6.0).

**Study Selection**

We applied the following eligibility criteria to identify eligible articles:

**Exclusion criteria:**
1. No original data: Paper does not contain original data (e.g., non-systematic review, editorial, letter with no original data).
2. Studies of multiple oral hypoglycemic drugs (e.g., sulfonylurea/metformin) where the effect of the sulfonylurea cannot be delineated.
3. Non-English title and abstract.
4. Article published in abstract form only.

**Inclusion criteria:** Good-quality and fair-quality studies in which

1. The patients were adults with Type 2 diabetes. Subgroups of interest will include, but are not limited to, different races, ages (older adult versus younger adult), and gender.

2. Intervention included either:
   - Sulfonylureas: chlorpropamide, glimepiride, glipizide, glyburide, tolazamide, tolbutamide (both immediate and extended release formulations included).
   - Short-acting secretagogues: repaglinide and nateglinide

3. For efficacy (lowering of HbA1c), study is a fair-or-better-quality systematic review or double-blind, randomized controlled trial (including crossover trials) in an outpatient setting (including emergency department).

4. Clinically relevant outcomes include:
   - Progression or occurrence of microvascular disease (nephropathy as evidenced by proteinuria/dialysis/transplant/end-stage renal disease, retinopathy including proliferative retinopathy and blindness, and neuropathy)
   - Progression or occurrence of macrovascular disease (cardiovascular disease and mortality, myocardial infarction, stroke, coronary disease, angioplasty/CABG, amputation)
   - Other complications of diabetes
   - Quality of life
   - All-cause mortality

5. To be included, reports about safety or adverse events had to report total withdrawals, withdrawals due to specific adverse events such as hypoglycemia, weight gain, or effects on lipids; or the frequency and severity of these specific adverse events. Controlled clinical trials, longitudinal cohort studies, and drug-drug interaction studies were eligible for inclusion.

When properly designed, direct comparator (“head-to-head”) trials provide the best-quality evidence to compare the efficacy and safety of different drugs. Direct comparator trials were available for some drug-drug comparisons.

Observational studies were eligible for the review of adverse events. Clinical trials are often not designed to assess adverse events, and may select low-risk patients (in order to minimize dropout rates) or utilize inadequately rigorous methodology for assessing adverse events. Observational studies designed to assess adverse event rates may include broader populations, carry out observations over a longer time period, utilize higher quality methodological techniques for assessing adverse events, or examine larger sample sizes.
Data Abstraction

One reviewer abstracted the following data from included trials: study design, setting, population characteristics (including sex, age, ethnicity, diagnosis), eligibility and exclusion criteria, interventions (dose and duration), comparisons, numbers screened, eligible, enrolled, and lost to follow-up, method of outcome ascertainment, and results for each outcome. We recorded intention-to-treat results if available and the trial did not report high overall loss to follow-up.

Validity Assessment

We assessed the internal validity (quality) of trials based on the predefined criteria listed in Appendix B, which were submitted to the Health Resources Commission in December 2001. These criteria are based on those developed by the US Preventive Services Task Force and the National Health Service Centre for Reviews and Dissemination (UK). We rated the internal validity of each trial based on the methods used for randomization, allocation concealment, and blinding; the similarity of compared groups at baseline; maintenance of comparable groups; adequate reporting of dropouts, attrition, crossover, adherence, and contamination; loss to follow-up; and the use of intention-to-treat analysis. Trials that had a fatal flaw in one or more categories were rated poor quality and were excluded from the review; trials which met all criteria, were rated good quality; the remainder were rated fair quality. As the “fair quality” category is broad, studies with this rating vary in their strengths and weaknesses: the results of some fair quality studies are likely to be valid, while others are only probably valid. A “poor quality” trial is not valid—the results are at least as likely to reflect flaws in the study design as the true difference between the compared drugs. External validity of trials was assessed based on whether the publication adequately described the study population, how similar patients were to the target population in whom the intervention will be applied, and whether the treatment received by the control group was reasonably representative of standard practice. We also recorded the funding source and role of the funder.

Appendix B also shows the criteria we used to rate observational studies of adverse events. These criteria reflect aspects of the study design that are particularly important for assessing adverse event rates. We rated observational studies as good quality for adverse event assessment if they adequately met six or more of the seven predefined criteria, fair if they met three to five criteria, and poor if they met two or fewer criteria.

Overall quality ratings for the individual study were based on ratings of the internal and external validity of the trial. A particular randomized trial might receive two different ratings: one for efficacy and another for adverse events. The overall strength of evidence for a particular key question reflects the quality, consistency, and power of the set of studies relevant to the question.

Data Synthesis

We summarized our results in evidence tables and in a narrative summary.
RESULTS

Overview

We identified a total of 1,108 citations, of which 27 were head-to-head trials of the included drugs. Twenty of these trials were excluded because they did not report any of the outcome measures selected for this review or because of poor- or poor-to-fair quality (internal validity.) (Appendix C) Most of the excluded poor-quality studies were small, did not compare baseline data or had major baseline differences, had high losses to followup, or excluded dropouts or nonresponders from the analysis and did not report enough information to calculate intention-to-treat results.

United Kingdom Prospective Diabetes Study

The largest head-to-head trial was the UK Prospective Diabetes Study. Unlike the other studies we found, the UKPDS addressed three of our key questions (glycemic control, outcomes, and adverse events), permitting a more complete comparison of the advantages and disadvantages of the compared drugs. Although it was an open study, it used adequate methods of randomization, was analyzed as an intention-to-treat study, had few dropouts, and examined several important clinical endpoints. Moreover the drugs it compared were not new to the market, reducing the chance of bias due to the lack of blinding.

The UKPDS was designed to address four questions:
1. Will improved blood glucose control by increasing insulin supply be beneficial or harmful?
2. Will insulin therapy or sulphonylurea therapy be particularly beneficial or harmful?
3. Will first- or second-generation sulphonylurea be particularly beneficial or harmful?
4. Will improving glucose control by enhancing insulin sensitivity with metformin be beneficial or harmful?

The first two questions are outside the scope of our review, but were examined in a recent, good-quality systematic review conducted for the US Preventive Services Task Force. That review concluded that the UKPDS was the best evidence available to support “intensive treatment” to control blood glucose in patients who have Type 2 Diabetes Mellitus. In the UKPDS, “intensive treatment,” or “tight control,” refers to a policy of increasing drug therapy to achieve a goal of normal fasting blood glucose levels. The UKPDS found that treatment with a sulfonylurea or insulin over the first 10 years after diagnosis of diabetes decreased the risk of microvascular disease. For all hypoglycemic drugs combined (insulin or a sulfonylurea), intensive glycemic control was associated with a 25% reduction in all microvascular endpoints combined, corresponding to a number needed to treat of 42 patients to prevent one event in 10 years. This difference was due primarily to a difference in the risk of having retinal laser photocoagulation (RR for intensive treatment 0.71, NNT=37 to prevent one event over 10 years.) No other clinical endpoints in the UKPDS reached statistical significance, but intensive treatment improved several intermediate endpoints (progression of retinopathy, proteinuria, two-fold increase in creatinine.) The number needed to treat to prevent one clinical endpoint was 19.6 (CI 10-500). The confidence interval indicates that intense glycemic control for 10 years prevents one or more complications of diabetes for every 10 to 500 patients treated.
The parts of the UKPDS of most interest in this review are described in Table 2 and in Figure 1. The largest, most important part of the UKPDS was the “main randomization” study, which is shown in bold in the figure. The UKPDS also provided data to compare the efficacy and safety of first- and second-generation sulphonylureas in a separate trial, called the “primary diet failure randomization.” (Table 2).

* Insulin and metformin were also comparators, but are excluded from the table because our focus is on comparisons among sulfonylureas.

Main randomization. In the “main randomization” population, 4,209 subjects who had fasting plasma glucose values between 6 mmol/l and 15 mmol/l were randomized to intensive treatment (70%) or to conventional treatment (30%). In patients randomized to intensive treatment, the goal of management was to get the fasting glucose below 6 mmol/l. At the first 15 sites, intensive treatment patients were randomized to insulin, chlorpropamide (up to 500 mg daily), or glyburide (up to 10 mg bid.) At the last 8 sites, patients were randomized to insulin, chlorpropamide or to glipizide (up to 20 mg bid.).

Many subjects initially assigned to intensive treatment with a sulfonylurea eventually developed a fasting blood glucose level higher than 6 mmol/l despite maximal doses. Until 1989, these subjects were maintained on monotherapy with the sulfonylurea unless their fasting glucose exceeded 15 mmol/l (if it did, insulin was added). From 1990 on, subjects who had fasting glucose levels ≥6 mmol/l despite maximal sulfonylurea therapy were re-randomized to either continue the sulfonylurea or to add metformin.

The goal of conventional treatment was to keep the fasting plasma glucose ≤15 mmol/l. If this could not be accomplished after one year or more of diet alone, the subject was re-randomized to one of the drug therapies, still with the goal of keeping the fasting plasma glucose ≤15 mmol/l. Most patients originally assigned to diet alone eventually required drug therapy.

Glycemic control. After 3 years of follow-up, there was no significant difference in HbA1c lowering between patients taking chlorpropamide (-0.4% change in HbA1c) and glyburide (-0.3% change). Fewer chlorpropamide patients required addition of a second drug (9% vs. 13%) but more chlorpropamide patients refused treatment or discontinued due to side effects (13% vs. 7%). As a result, the actual number of patients maintained on their assigned therapy was the same for both drugs (78% vs. 79%).

After 6 years, there was no significant difference in HbA1c between chlorpropamide (-0.3% change in HbA1c) and glipizide (-0.2% change) in HbA1c.(Wright UKPDS)

At the 10 year followup assessment, patients who had been assigned to any intensive treatment (insulin or sulfonylureas) had lower HbA1c levels than conventionally treatment patients (7.0% and 7.9%, p<0.0001). After 10 years the net change in HbA1c was –0.38% for chlorpropamide and +0.11% for glyburide (p=0.008). Note that these results are based on an
intention-to-treat analysis: By ten years, most patients in both groups were taking combination therapy (the original sulfonylurea plus metformin) or insulin.

Need for additional therapy. At 6 years, of 1305 patients randomized to intensive therapy with a sulfonylurea, 44% were on combination therapy with a second agent. (Matthews UKPDS 26) More patients assigned to intensive treatment with chlorpropamide (72%, CI 66% to 77%) were on monotherapy than patients assigned to intensive treatment with glyburide (60%, CI 54% to 66%).

Outcomes. The UKPDS investigators also compared outcomes after 10 years of intensive treatment with chlorpropamide (n=619) or glyburide (n=615). No direct comparisons of outcome for chlorpropamide vs. glyburide were statistically significant, but chlorpropamide had less favorable results than glyburide when compared to conventional therapy. For example, compared with conventional therapy, the NNT to prevent any diabetes-related endpoint was 17 for intensive treatment with glyburide (RR 0.82; 0.69-0.97, p=0.018), but it was 57 for intensive chlorpropamide (RR 0.93; 0.79-1.99, p=36). For the combined microvascular endpoint, the NNT for glyburide vs. conventional therapy was 27 (RR 0.66, CI 0.47 to 0.93, p=0.017), but it was 70 for chlorpropamide vs. conventional therapy (RR 0.86, CI 0.63 to 1.17, p=0.33). Patients assigned to chlorpropamide also did not have the same risk reduction in progression to retinopathy as glyburide or insulin at 12 years (p=0.0056).

No outcome data have been reported for glipizide.

Adverse events. In the UKPDS (UKPDS 13) intensive treatment group, 13% of chlorpropamide patients refused treatment or discontinued due to side effects, versus 7% of glyburide patients.

Weight gain and hypoglycemic episodes were significantly raised by any intensive drug treatment. Patients assigned to chlorpropamide gained more weight than those assigned to glyburide. Over 10 years, compared with the conventional therapy group, chlorpropamide patients gained 2.6 kg more (1.6-4.9, p<0.0001), glyburide patients gained 1.7 kg more (0.7-2.7, p<0.001), and insulin patients gained 4.0 kg more (3.1-4.9, p<0.0001).

Identical proportions of patients had hypertension before entering the study, but after 10 years, chlorpropamide subjects were more likely to be on therapy for hypertension (43% vs. 36%, p=0.022). Patients assigned chlorpropamide also had significantly higher systolic and diastolic blood pressure at 6 years (143/82 mm Hg vs. 138/80 mm Hg on other therapies, p<0.001). Adjusting for the difference in mean systolic or diastolic blood pressure by logistic regression analysis did not change this finding.

In the intention-to-treat population (UKPDS 33), major (severe) hypoglycemic episodes at 10 years with chlorpropamide and glyburide were 1.0% and 1.4%, respectively, compared to 0.7% for diet. Compared with chlorpropamide, glyburide was associated with a higher frequency (16% vs. 21%) and a higher annual rate of hypoglycemic episodes (0.4% for chlorpropamide, 0.6% for glyburide, 0.1% for diet therapy.) The UKPDS was designed to re-examine whether intensive treatment increases the risk of cardiac events, as had been reported in an earlier trial for tolbutamide (University Group Diabetes Program UGDP) and in a VA cooperative study of intensive insulin therapy. In the UKPDS, there was no adverse effect of tight control on cardiovascular outcomes.

For glipizide, adverse event data from the UKPDS have not been reported fully. A partial report of glycemic control at six years found no difference in the annual rate of hypoglycemic episodes between chlorpropamide (1.8%) and glipizide (1.4%). Weight gain with
chlorpropamide was significantly higher at +4.0 kg compared to glipizide +2.8 kg (p=0.048), but was not significantly different when adjusted for initial weight.

**Primary diet failure randomization.** This trial compared insulin, sulfonylureas, and metformin in patients who had fasting blood glucose levels greater than 15 mmol/l despite up to 3 months of diet therapy. A partial report of the results of this part of the UKPDS was published in 1998. By 6 years, 62% of patients assigned to chlorpropamide and 69% patients assigned to glyburide required additional therapy (addition of metformin, addition of insulin, or change to insulin.) More major hypoglycemic episodes occurred in this population than in the “main randomization” population. By 6 years, the annual rate of serious (major) hypoglycemic episodes was 2.5% (0.0-6.7) for glyburide and 1.5% (0.0-2.6) for chlorpropamide.

1. **For adult patients with Type 2 diabetes, do oral hypoglycemics differ in the ability to reduce HbA1c levels?**

**Head-to-head trials.** There was a great gap in quality and relevance between the UK Prospective Diabetes Study and the other 6 head-to-head trials that assessed efficacy, summarized in Table 3 and in Appendix D. Although the studies varied in baseline plasma glucose levels, prior treatments, and length of followup, the results were consistent: there was a small absolute change in HbA1c with these agents, only apparent after at least 8 weeks of therapy, and diminishing in time. There were no significant differences in 6 of the 7 trials that followed patients for 15 months or less. The non-sulfonylurea secretagogue repaglinide was found to be superior to glipizide in one fair study, but the dosage of glipizide was maximized at 15 mg, while it is labeled for use up to 40mg. Additionally, only 50% of patients received the 15 mg dose.

We did not identify any trials comparing the first-generation sulfonylureas tolazamide and tolbutamide to other sulfonylureas or to non-sulfonylurea secretagogues.

Placebo-controlled trials. One fair-quality systematic review compared oral hypoglycemic drugs in type 2 diabetics.¹⁴ It included 63 trials of oral agents, most of which were comparisons to placebo rather than direct comparator trials. The authors found no difference in the efficacy within or between the sulfonylureas and the non-sulfonylurea secretagogues.

2. For adult patients with Type 2 diabetes, do oral hypoglycemics differ in the progression or occurrence of clinically relevant outcomes?

Only the UKPDS provides evidence on this question, and only for the comparison of chlorpropamide to glyburide. The results of the UKPDS are discussed above.
3. For adult patients with Type 2 diabetes, do oral hypoglycemics differ in safety or adverse events?

**Adverse Events.** The UKPDS provides the best available data on adverse effects of long-term use of chlorpropamide or glyburide. So far it has not reported the results for glipizide. Results of the UKPDS were described above.

There are no comparable data for other sulfonylureas or for the newer secretagogues. There were no significant differences in weight and lipid changes in the other head-to-head trials (Table 4), except for a small difference in HDL. One trial found a slight increase in HDL-C.

**Table 4. Adverse events in head-to-head trials.**

*Adapted from Facts and Comparisons

**Alcohol may cause a disulfiram-like reaction with chlorpropamide

4. Are there subgroups of patients based on demographics (age, racial groups, gender), concomitant medications, co-morbidities (i.e. obesity), or history of hypoglycemic episodes for which one oral hypoglycemic is more effective or associated with fewer adverse effects?

Cross-sectional data reveal important differences among racial groups in the presentation and course of diabetes. However, there is no direct evidence that any sulfonylurea or non-sulfonylurea secretogogue has an advantage in efficacy for any racial group. In placebo-controlled trials presented to the FDA during the approval process for glimeripide, no differences were found in the antihyperglycemic effect between whites (n = 536), blacks (n = 63), and Hispanics (n = 63) who had Type 2 diabetes. Similarly, in a U.S. 1-year study in patients with type 2 diabetes, the blood glucose-lowering effect of repaglinide was comparable between Whites (n=297) and African-Americans (n=33). Repaglinide had similar pharmacokinetics in Whites (n=74) and Hispanics (n=33). Pharmacokinetic data on nateglinide found no differences among several races and ethnic groups.

Old age is a risk factor for serious hypoglycemic. (Ben-Ami, Arch Int Med 1999) An observational study attempted to make the case that longer-acting sulfonylureas were associated with a higher risk of suffering hospitalization for hypoglycemia. Specifically, the authors noted that, at a time when 23.5% of the population with Type 2 diabetes took a long-acting drug, over 40% of hospitalizations due to hypoglycemia were associated with long-acting drugs. In the UKPDS trial, however, patients assigned to chlorpropamide had fewer hypoglycemic events than those taking glyburide. In another trial, glipizide and glyburide did not differ in efficacy or adverse events in an elderly population.

SUMMARY

Table 6 summarizes the results of this review.

REFERENCES

Newly Diagnosed Diabetic Patients

Fasting Plasma Glucose (FPG) >6mol/l

3-month dietary run-in

“Main randomization” group
FPG >6 and <=15 mmol/L on diet

Conventional treatment
(diet alone with goal FPG<15 mmol/L )

2nd randomization if FGP>=15 mmol/L

Insulin
Sulfonylurea
Metformin
Chlorpropamide
Glyburide
Glipizide

Intensive treatment
(goal of FPG<6 mmol/L)

Sulphonylurea*
Insulin
Metformin (obese subjects in Glucose Study I)

“Diet satisfactory” group
FPG <=6 mmol/L on diet

Insulin
Sulphonylurea
Metformin (obese subjects in Glucose Study I)

“Primary diet failure” group
FPG >15 mmol/L on diet. Randomized to:

Sulphonylurea
Insulin
Chlorpropamide
Glyburide
Glipizide

Figure 1. UKPDS trial design. Diagram based on information in UK Prospective Diabetes Study Group, “UK Prospective Diabetes Study (UKPDS). VIII. Study design, progress, and performance.” Diabetologia (1991).34:877-890.

*Until 1989, sulfonylurea alone was used even if the FPG rose to 15 mmol/L; above 15 mmol/L, metformin was added. From 1990 on, patients taking a sulfonylurea were re-randomized to add metformin for FPG>6 mmol/L or to continue sulfonylurea alone until FPG rose above 15 mmol/L.
Figure 2. Results of search and selection of included articles

1104 potentially relevant citations

- 850 Excluded:
  - 581 did not evaluate included patients or intervention, were kinetic studies, foreign language, abstract only or without abstracts
  - 149 were reviews
  - 120 were case reports, letters, conference proceedings, or evaluating the metabolic disease itself

215 trials retrieved for more detailed evaluation
- 39 background articles retrieved

- 204 trials excluded:
  - 83 wrong design (dose-ranging, placebo-controlled, conversion, or pharmacokinetic study)
  - 89 wrong agent, patients or outcome
  - 22 poor quality
  - 10 agents unavailable in U.S.

11 head-to-head trials included in systematic review (5 of the 11 trials were from UKPDS)

Methods for Drug Class Reviews
for Oregon Health Plan Practitioner-Managed Prescription Drug Plan
Oregon Health & Science University Evidence-based Practice Center
December 14, 2001

Quality Criteria

Assessment of Internal Validity
To assess the internal validity of individual studies, the EPC adopted criteria for assessing
the internal validity of individual studies from the US Preventive Services Task Force
and the NHS Centre for Reviews and Dissemination.

For Controlled Trials:

Assessment of Internal Validity

1. Was the assignment to the treatment groups really random?
   Adequate approaches to sequence generation:
   Computer-generated random numbers
   Random numbers tables
   Inferior approaches to sequence generation:
   Use of alternation, case record numbers, birth dates or week days
   Not reported

2. Was the treatment allocation concealed?
   Adequate approaches to concealment of randomization:
   Centralized or pharmacy-controlled randomization
   Serially-numbered identical containers
   On-site computer based system with a randomization sequence that is not
   readable until allocation
   Other approaches sequence to clinicians and patients
   Inferior approaches to concealment of randomization:
   Use of alternation, case record numbers, birth dates or week days
   Open random numbers lists
   Serially numbered envelopes (even sealed opaque envelopes can be
   subject
   to manipulation)
   Not reported

3. Were the groups similar at baseline in terms of prognostic factors?

4. Were the eligibility criteria specified?

5. Were outcome assessors blinded to the treatment allocation?

6. Was the care provider blinded?
7. Was the patient kept unaware of the treatment received?

8. Did the article include an intention-to-treat analysis, or provide the data needed to calculate it (i.e., number assigned to each group, number of subjects who finished in each group, and their results)?

9. Did the study maintain comparable groups?

10. Did the article report attrition, crossovers, adherence, and contamination?

11. Is there important differential loss to followup or overall high loss to followup? (give numbers in each group)

Assessment of External Validity (Generalizability)

1. How similar is the population to the population to whom the intervention would be applied?

2. How many patients were recruited?

3. What were the exclusion criteria for recruitment? (Give numbers excluded at each step)

4. What was the funding source and role of funder in the study?

5. Did the control group receive the standard of care?

6. What was the length of followup? (Give numbers at each stage of attrition.)

For Reports of Complications/Adverse Effects

Assessment of Internal Validity

1. Was the selection of patients for inclusion non-biased (Was any group of patients systematically excluded)?

2. Is there important differential loss to followup or overall high loss to followup? (Give numbers in each group.)

3. Were the events investigated specified and defined?

4. Was there a clear description of the techniques used to identify the events?

5. Was there non-biased and accurate ascertainment of events (independent ascertainer; validation of ascertainment technique)?

OHSU EPC Methods
6. Were potential confounding variables and risk factors identified and examined using acceptable statistical techniques?

7. Did the duration of followup correlate to reasonable timing for investigated events? (Does it meet the stated threshold?)

Assessment of External Validity

1. Was the description of the population adequate?

2. How similar is the population to the population to whom the intervention would be applied?

3. How many patients were recruited?

4. What were the exclusion criteria for recruitment? (Give numbers excluded at each step)

5. What was the funding source and role of funder in the study?

Economic Studies

Assessment of Internal Validity

Framing

1. Was a well-defined question posed in answerable form?

2. Was a comprehensive description of the competing alternatives given?

3. Are the interventions and populations compared appropriate?

4. Is the study conducted from the societal perspective?

5. Is the time horizon clinically appropriate and relevant to the study question?

Effects

1. Are all important drivers of effectiveness included?

2. Are key harms included?

3. Is the best available evidence used to estimate effectiveness?

4. Are long-term outcomes used?
5. Do effect measures capture preferences or utilities?

**Costs**

1. Are costs and outcomes measured accurately?

2. Are costs and outcomes valued credibly?

3. Are costs and outcomes adjusted for differential timing?

4. Are all appropriate downstream medical costs included?

5. Are charges converted to costs appropriately?

6. Are the best available data used to estimate costs? (like first question)

7. Are all important and relevant costs and outcomes for each alternative identified?

**Results**

1. Are incremental cost-effectiveness ratios presented?

2. Are appropriate sensitivity analyses performed?

3. How far do study results include all issues of concern to users?

**Assessment of External Validity**

1. Are the results generalizable to the setting of interest in the review?

Method for assessing adverse events not stated. | |
| Rosenstock 1993 |         | 1. Washout period, then open multicenter randomized trial of glyburide (n=70) vs. glipizide (n=69) with a titration phase and maintenance phase.  
Total followup time was 4 months.  
2. Eligibility: Type 2 diabetics 65 years or older who had been well-controlled with a sulfonylurea | Poor-quality.  
Differential loss to followup: 21.4% of glyburide patients and 43.5% of glipizide patients did not complete the study.  
Only subjects who completed the study were included in the efficacy analysis. | After 4 months there were no differences in Hgb A1c or in adverse events. |
| Simic 1991 | Southern Med Journal | 1. 8-week period of previous therapy with glyburide (n=16) or glipizide (n=10), then changed to the other drug, titrated, then followed for 8 more weeks.  
2. Eligibility: Type 2 diabetics who had a fasting blood glucose level greater than 8.3 mmol/L (150 mg/dL) on glyburide or glipizide | Ineligible: pre-post design, not randomized or blinded, no eligible outcome measures. | Designed to test the efficacy of switching from sulfonylurea to another.  
Fasting blood glucose levels did not improve after switching from glyburide to glipizide or from glipizide to glyburide. |

<tr>
<td>Damsbo 1999</td>
<td>Diabetes Care</td>
<td>1. Double-blind randomized trial of repaglinide (n=42) vs. glyburide (n=41). After titrating the medication dose, patients who had fasting blood glucose levels 110-180 entered the 3-day study&lt;br&gt;2. Type 2 diabetics aged 40-75, most had been treated with sulfonylureas.</td>
<td>No eligible outcome measures. 25 glyburide patients and 17 repaglinide patients were included in the analysis, but all were included in the safety analysis</td>
<td>Unusual design to test the effect of accidental dietary noncompliance by giving well-controlled diabetics 2 instead of 3 meals. There were more adverse events in the repaglinide patients (9/42) than in glyburide patients (5/41). Their severity was measured but not reported. There were 4 episodes of symptomatic hypoglycemia in the glyburide patients after the skipped meal, but none in the repaglinide group. There were no differences in the frequency of low blood glucose.</td>
</tr>
<tr>
<td>Marbury 1999</td>
<td>Diab Res &amp; Clin Pract</td>
<td>1. One-year multicenter randomized double-blind trial of repaglinide (n=383) vs. glyburide (n=193).&lt;br&gt;2. Eligibility: Type 2 diabetics 37-75 years old, most previously treated with oral hypoglycemics.&lt;br&gt;3. Maximum dose: glyburide—15 mg/day&lt;br&gt;repaglinide—12 mg/day</td>
<td>Fair-poor quality. Only 331 of 576 (57%) completed the study; efficacy analysis was not by intention-to-treat, but adverse event analysis was.</td>
<td>No difference in Hgb A1C at 1 year. Adverse events any: repaglinide 30% glyburide 28% hypoglycemia: repaglinide 15% glyburide 19%</td>
</tr>
<tr>
<td>Wolffebuttell 1993</td>
<td>Eur J Clin Pharm</td>
<td>1. Open randomized blocks, not concealed, double-blind controlled trial of glyburide (n=15) vs. repaglinide (n=29) with 12 weeks of followup.&lt;br&gt;2. Eligibility: unclear, most had been taking glyburide&lt;br&gt;3. Maximum dose: repaglinide —4 mg&lt;br&gt;glyburide—15 mg</td>
<td>Poor-quality. Allocation not concealed, inadequate baseline data, some baseline differences (body weight), and open design in subjects who had taken one of the study drugs.</td>
<td>No difference in Hgb A1C or weight.</td>
</tr>
